# Illinois Corn Performance Tests Results for 1934

LODGING RESISTANCE

TOTAL YIELD

SOUND CORN

QUALITY

UNIVERSITY OF ILLINOIS  
AGRICULTURAL EXPERIMENT STATION  
BULLETIN 411

IN COOPERATION WITH THE DIVISION OF CEREAL CROPS AND DISEASES, BUREAU OF  
PLANT INDUSTRY, U. S. DEPARTMENT OF AGRICULTURE, AND THE ILLINOIS STATE  
NATURAL HISTORY SURVEY

**T**HE GREAT NEED in all sections of Illinois is for corn that not only is more resistant to lodging and capable of higher yields, but is of better quality, more resistant to disease, to drouth, cold, and insect pests, and that will use most advantageously the available supplies of plant nutrients in the soil.

Obviously it is only by the active cooperation of workers interested in these different phases of corn improvement that progress can be made in the development and distribution of seed better adapted to the varying conditions obtaining in the different sections of the state. The corn performance tests reported herein are therefore part of a coordinated corn improvement program being conducted cooperatively by the Illinois Agricultural Experiment Station, the U. S. Department of Agriculture, and the Illinois State Natural History Survey.

This search for corn of better quality—corn better suited to the use to which it is to be put, whether for feeding on the farm or for commercial purposes—may be expected to lead eventually to a more intensive study of the chemical composition of both grain and stover. However, it is to some of the other basic problems that attention is at present directed.

# Illinois Corn Performance Tests

## Results for 1934

By G. H. DUNGAN, J. R. HOLBERT, W. J. MUMM, J. H. BIGGER,  
and A. L. LANG<sup>1</sup>

THE SECTIONS of Illinois in which corn is grown intensively and where it constitutes the most important cash crop differ widely in type and productivity of soil as well as in climatic characteristics such as rainfall, summer temperatures, and length of favorable growing season. Corn diseases also vary in severity from one part of the state to another, especially from north to south; and certain insect pests that may not exist in some sections become serious problems in others.

As a step toward finding for the different sections of Illinois the best available corn varieties and hybrids and aiding in the further development of desirable varieties and hybrids, 177 different kinds of corn were tested for yield and quality at twelve different places in the state in 1934, these twelve places being representative of the principal corn-growing districts (Fig. 1).

The location of the fields, the names of the cooperators, a brief description of the season, and indication of the intensity of second-brood chinch bug infestation, together with the average yield of all entries at a given location, are recorded in Table 1. More detailed description of the season is given on pages 58 and 59.

### Numbers and Kinds of Entries in the Tests

Of the 177 different kinds of corn included on the 13 fields (12 different localities) in 1934, 45 were open-pollinated varieties and 132 were hybrids. In the accompanying tables these entries are grouped into two general classes—"Regular" and "Experimental." In the "Regular" group are placed the varieties and hybrids that may be considered to be in commercial production, 100 bushels or more of seed being available for planting in 1935, or having been available in that amount in previous years. In the "Experimental" group are included those varieties and hybrids of which only small amounts of seed have been produced for planting in 1935.

In order to have some measure of the general level of performance

<sup>1</sup>G. H. DUNGAN, Associate Chief in Crop Production, Illinois Agricultural Experiment Station; J. R. HOLBERT, Senior Agronomist, U. S. Department of Agriculture; W. J. MUMM, Associate in Plant Breeding, Illinois Agricultural Experiment Station; J. H. BIGGER, Field Entomologist, Illinois State Natural History Survey; and A. L. LANG, Assistant Chief in Soil Experiment Fields, Illinois Agricultural Experiment Station.

of the corn ordinarily grown in the community, composite samples of local seed of open-pollinated corn were obtained for some localities. At three localities these samples were furnished by the agricul-

FIG. 1.—LOCATION OF 1934 TEST FIELDS, AND AVERAGE CORN YIELDS, 1928-1932

(Production map prepared by Division of Agricultural Statistics, Illinois State Department of Agriculture cooperating with the U. S. Department of Agriculture.)

tural department of the local high school, 12 to 30 boys contributing a half pint of shelled corn from their fathers' seed supply. At two places a composite sample was obtained by collecting seed from about 20 planter boxes the day before the tests were planted.

### Planting and Arrangement of Entries

The experimental trials on the farms of the cooperators were located in fields larger than that required for the test, in order that the corn in the test might be entirely surrounded by other corn, and also in order that the test might be conducted under average conditions

TABLE 1.—ILLINOIS COOPERATIVE CORN PERFORMANCE TESTS, 1934: GENERAL INFORMATION\*

Location of field	County	Cooperator	Number of entries in test	Date planted	Kind of season	Date harvested	Average total yield	Average sound corn
							bu.	bu.
Stockton Rochelle	Jo Daviess	Homer Curtiss	21	May 11	Generally favorable	Dec. 4	84.2	83.0
	Ogle	G. A. Lazier and Son	31	May 10	Very dry; hot winds; light chinch bug infestation	Dec. 3	45.9	33.3
DeKalb	DeKalb	Ill. Agr. Exp. Sta., Agronomy	20	May 16	Very dry; hot winds	Nov. 30	29.6	17.6
Galesburg	Knox	John Sullivan	36	May 4	Dry; early heavy chinch bug infestation	Nov. 19	55.8	38.4
Granville	Putnam	Ben Moews	40	May 12	Very dry; early heavy chinch bug infestation	Nov. 28	34.4	14.9
Minier	Tazewell	Ray Kettering	36	May 8	Dry; late light chinch bug infestation	Nov. 23	76.6	68.7
Rankin	Vermilion	Ill. Agr. Exp. Sta., Agricultural Economics	33	May 7	Very dry; light chinch bug infestation	Nov. 7	26.2	....
Urbana S. W. R.	Champaign	Ill. Agr. Exp. Sta., Agronomy	36	May 14	Dry; late heavy chinch bug infestation	Nov. 6	65.1	52.6
Urbana S. C. R.	Champaign	Ill. Agr. Exp. Sta., Agronomy	36	May 15	Dry; early heavy chinch bug infestation	Dec. 12	52.3	43.1
Tolono	Champaign	Charles Meharry	40	May 9	Dry; late light chinch bug infestation	Dec. 10	55.0	40.7
Alexander	Morgan	H. D. Kamm	25	May 8	Very dry; hot winds; light chinch bug infestation	Dec. 5	18.3	8.0
Edgewood	Effingham	F. V. Wilson and Son	11	May 3	Early moderate chinch bug infestation	Oct. 16	33.7	....
Alhambra	Madison	Ill. Agr. Exp. Sta., Agronomy	15	May 2	Very dry; light chinch bug infestation	Nov. 20	13.2	....

\*For the names and addresses of those who contributed seed for the 1934 Corn Performance Tests, see pages 63 and 64.

encountered on the farm. Planting was done by hand on the day the rest of the field was planted. The rows were made to join with those of the adjoining corn so that the cooperators could cultivate the plot along with the corn in the rest of the field.

Each entry (variety or hybrid) occupied a space 12 hills long and two rows wide. In order to obtain a good distribution over the test field and so insure comparable yields between the different entries, each entry was assigned a number and distributed in a random manner in each of the 10 replications. The planting plan used at the Alexander field is shown in Fig. 2. Plans similar to this one were used on the other fields, with the exception of the smaller fields at Edgewood and Alhambra, which were planted in strips with frequent checks.

FIG. 2.—PLANTING PLAN SHOWING CONTROLLED RANDOM DISTRIBUTION

The plantings were in five series (S-1, etc.) with each series including two replications (R-1, etc.) of all entries. Each entry appears once and only once in each of the ten replications; it also appears only once in each vertical block of plots five plots wide by five plots long. The plots were so distributed in each replication that very rarely was an entry planted alongside the same two entries more than once in the entire experiment. Plot 15 has been blackened to make it easier to see how, by this plan, a single entry is distributed over the ten replicated plots.

### An Unusual Season

The weather and other factors affecting corn in 1934 were unusual in many respects. The dry condition of the soil at planting time resulted in good stands in only the most carefully planted fields or series.

Excellent stands, however, were obtained where sufficient care was taken to plant the corn deeply enough to be surrounded by moist soil. The data on series in which there were very irregular stands and the corn was late in germinating because of too shallow planting were not included.

Shortage of moisture thruout the season resulted in stunted vegetative development. In some localities hot, dry winds at pollination time caused either barrenness or incompletely filled ears. In all localities, burning of the tassels and upper blades was rather general. This blighting effect of the heat was especially noticeable with certain entries susceptible to drouth and heat injury.

At Rochelle and DeKalb the heat and drouth injury was not complicated by heavy chinch bug infestation; and, in general, this was true also at Rankin, Alexander and Alhambra.

Second-brood chinch bug infestation was very heavy on the Granville, Galesburg, and Urbana fields; and in these fields chinch bug resistance, in addition to resistance to heat and drouth, was an important factor in determining the comparative performance rating of the different entries. In the other fields in central and southern Illinois, where injury from bugs was somewhat less, the relative performance furnishes a less dependable index of chinch bug resistance.

The average yields on the different fields, as recorded in Table 1, reflect to a considerable extent the productivity levels of these fields. Coupled with the yields of sound corn, they also serve as an index of the climatic conditions, intensity of chinch bug infestation, amount of ear worm and ear rot damage, and other disturbing factors.

### Measuring the Performance of Entries

Important as yielding capacity admittedly is in the choice of the best varieties or hybrids to grow, it is not the only important consideration. A strain selected should stand up reasonably well during the normal corn-harvesting period, the ears should mature well in a normal season and have a minimum amount of rot and of weather-damaged grain.

The characteristics that have therefore been taken into consideration in an attempt to evaluate the comparative desirability of the entries in these performance tests are (1) *lodging resistance*, (2) *general quality of grain*, (3) *total yield*, and (4) *sound yield*. The average of separate ratings on each of these qualities constitutes the general performance rating for an entry and is the basis for the rank given an entry in the accompanying tables.

1. *Lodging Resistance*.—Lodging resistance was measured in the following way. Just before harvest at least two men examined each entry and estimated the percentage of plants that were erect. Whether lodging was due to broken stalks or to weak roots, it was recorded in the same way. Stalks broken above the ears were considered good stalks. The average of all the estimates made on all the replications of a given entry in a given field constituted the lodging resistance rating of that particular entry (Fig. 3).

FIG. 3.—LODGING RESISTANCE OF CORN ON TWO PLOTS IN TEST

Lodging resistance was included among other qualities in giving the entries a general performance rating. (*Left*) An open-pollinated variety with a lodging resistance rating of 30 on this particular plot and 20 as an average of all ten plots in the field. (*Right*) A promising hybrid having a lodging resistance of 90 on the plot shown and an average of 69 for all ten plots in the field. Photograph was taken December 12, 1934.

2. *Sound Corn Yield*.—In order to get as good a measure as possible of the resistance of the entries to ear rot, the corn in these tests was, for the most part, harvested late in the season. At the time of harvest all the corn from each 2-by-12-hill planting was weighed, then dumped on the ground and the ears sorted into piles of sound corn and damaged corn.

The ears classed as sound were comparatively well matured and not visibly rotted. Ears placed in the damaged pile included unmistak-

ably immature or "chaffy" ears and those visibly rotted. The ear worm damage on some ears was followed by rot of such severity that the ears were placed in the damaged class.

The rating of any given entry with respect to yield of sound corn is based on its performance in relation to that of all the other entries on the same field, the yield of sound corn from each replication of an entry being averaged and expressed as a percentage of the average yield of sound corn from all the entries on the field, including that of the farmers' composite.

3. *General Quality*.—Anyone who has attempted to sort ears of corn into sound and damaged classes realizes the difficulties involved

TABLE 2.—QUALITY RATING AND SOUND CORN: AVERAGE OF DATA ON TWELVE FIELDS IN ILLINOIS, 1934

Location of field	Average general quality rating	Average classed as sound (based on total yield)
		<i>perct.</i>
Stockton.....	85.2	98.6

Edgewood.....	74.4	(*)

\*No data taken.

in adhering consistently to a given standard and also in giving proper weight to all the different kinds and degrees of gradation from the standard.

In the first place the tendency to include lower quality corn in the sound class is much greater when the sample is all of inferior quality. The above method of evaluating quality therefore tends to give low-grade entries a relatively higher rating than they should have, and entries of high quality a relatively lower rating than they should have. Furthermore an entry may contain a high proportion of ears that are relatively immature from various causes yet not of low enough quality or sufficiently "chaffy" to be classed in the damaged group. Again the sound corn of some entries may show rather consistently greater

damage from ear worms than that of other entries with equally high yields of sound corn. The amount of weather damage that has resulted from poor husk covering also varies markedly in the sound corn.

In order, therefore, to obtain a more accurate rating of the quality of the grain from the different entries, two or more experienced men estimated the *general quality* of each entry. One hundred was used as the rating for an entry having every ear fully matured and sound, and 0 for an entry all of which was so badly damaged as to be practically worthless even for feeding. Entries having sound ears that were not fully matured or were low in quality for other reasons were marked down in proportion to their deviation from the standard, and chaffy or immature ears classified as damaged were given credit for having some feeding value.

The average of all the individual estimates of the quality of all the replications of a given entry on a given field constitutes, in the accompanying tables, the *general quality* rating for that entry.

*Total Yield.*—All yields were calculated on the basis of shelled corn containing 16.0 percent moisture, except for the yields on the Alexander and Edgewood fields, which were corrected to 15.5 percent.

In arriving at the rating of any given entry with respect to total yield, the average yield of corn from all the replications of the entry is expressed as a percentage of the average yield from all the entries on the field, including that of the farmers' composite.

### Hybrids Proved Superior to Open-Pollinated Varieties

The detailed performance of all entries on the thirteen different fields in the Illinois tests are given in Tables 3 to 18. In these tests the best commercial hybrids proved far superior to the leading open-pollinated varieties; and the better experimental hybrids were distinctly better than the best commercial hybrids.

The above statement is based on the fact that on the ten fields where comparisons were possible, the five open-pollinated varieties had an *average performance rating* of 71.7; the five best commercial hybrids, 86.0; and the five best experimental hybrids, 96.5. The average yield of sound corn from all the open-pollinated varieties was 33.4 bushels; from the commercial hybrids, 39.0 bushels; and from the experimental hybrids, 46.3 bushels an acre.

The hybrids having high performance records showed as much adaptational range from north to south and east to west as did the best open-pollinated varieties. Many of the hybrids showed great capacity to endure the drouth and heat of the 1934 season.

### Entries Varied in Capacity to Utilize Plant Nutrients

In their ability to utilize the plant-food materials present in the soil, some entries showed a much higher degree of efficiency than others, as evidenced by the differences in the yields from the same variety or hybrid on fields that varied widely in productive capacity.

The results from the two fields at Urbana demonstrate this point very clearly. One field, the Southwest rotation, growing corn, oats, clover, and wheat, has soil of high productive capacity. The other field, the South-Central rotation, growing corn, corn, corn, and soybeans, has soil of medium productive capacity. Some entries showed much greater differences than did others between their yields on the better soil and their yields on the medium soil. One entry, for example, yielded only 5 additional bushels of sound corn an acre on the better soil than on the medium soil; while another entry, which also yielded more on the medium soil, responded to the better soil to the extent of producing 24.4 more bushels on it, than on the medium soil.

This ability of some varieties and hybrids to respond more markedly than others to a better soil—that is, to take advantage of the greater supply of available plant foods in the better soil—is in agreement with unpublished data obtained over a period of years by E. E. DeTurk and J. R. Holbert and with data from the Hartsburg soil experiment field the past year.

Thus the kind of soil on which corn is to be grown must also be taken into consideration when selecting seed for a given locality or field, for the highest yielding variety on one field will not necessarily be the highest yielding variety on another of different productive capacity.

FIG. 4.—A BUSHEL OF SHELLED CORN FROM EACH OF TWO HIGH-YIELDING HYBRIDS ON A CENTRAL ILLINOIS FIELD

These two hybrids were about equal in lodging resistance (above 80) and in total yield. One, however, had 17.3 percent commercially damaged grain and the other only 2.8 percent. The former would grade "Sample" on the market and the other "No. 2."
